Age is the dominant risk factor for infectious diseases, but the mechanisms linking age to infectious disease risk are incompletely understood. Age-related mosaic chromosomal alterations (mCAs) detected from genotyping of blood-derived DNA, are structural somatic variants indicative of clonal hematopoiesis, and are associated with aberrant leukocyte cell counts, hematological malignancy, and mortality. Here, we show that mCAs predispose to diverse types of infections. We analyzed mCAs from 768,762 individuals without hematological cancer at the time of DNA acquisition across five biobanks. Expanded autosomal mCAs were associated with diverse incident infections (hazard ratio (HR) 1.25; 95% confidence interval (CI) = 1.15-1.36; $P = 1.8 \times 10^{-7}$), including sepsis (HR 2.68; 95% CI = 2.25-3.19; $P = 3.1 \times 10^{-28}$), pneumonia (HR 1.76; 95% CI = 1.53-2.03; $P = 2.3 \times 10^{-15}$), digestive system infections (HR 1.51; 95% CI = 1.32-1.73; $P = 2.2 \times 10^{-9}$) and genitourinary infections (HR 1.25; 95% CI = 1.11-1.41; $P = 3.7 \times 10^{-4}$). A genome-wide association study of expanded mCAs identified 63 loci, which were enriched at transcriptional regulatory sites for immune cells. These results suggest that mCAs are a marker of impaired immunity and confer increased predisposition to infections.

ith advancing age comes increased susceptibility to infectious diseases^{1,2}. Immunosenescence is the age-related erosion of immune function, particularly with respect to adaptive immunity³⁻⁶. Leukocytes, including T cells and B cells, are key mediators of adaptive host defenses against infections, with

impaired immune responses increasing the risk for infections⁷⁻⁹. Age-related mosaic chromosomal alterations (mCAs) detected from blood-derived DNA are clonal structural somatic alterations (deletions, duplications, or copy number neutral loss of heterozygosity (CNN-LOH)) present in a fraction of peripheral leukocytes that can

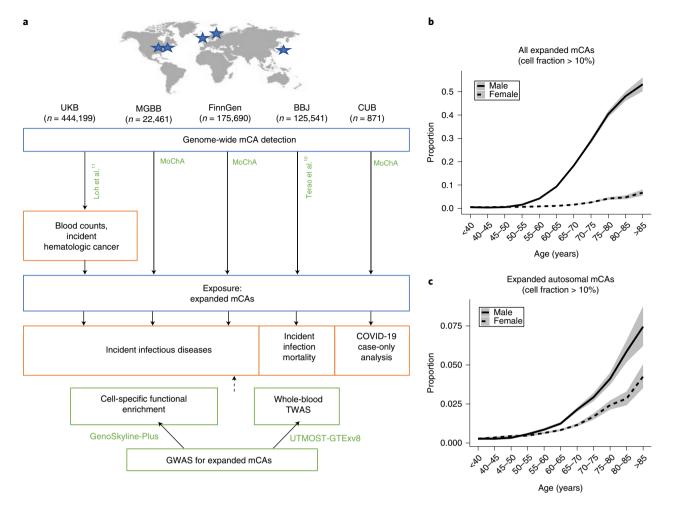

Fig. 1] Schematic diagram of the study flow, and distribution of mCAs with age and sex. a, Genome-wide mCAs were detected across the UKB¹¹, MGBB (via the MoChA pipeline, https://github.com/freeseek/mocha), FinnGen (via the MoChA pipeline), BBJ¹⁰ and CUB (via the MoChA pipeline) cohorts. The association of expanded mCAs (cell fraction > 10%) with incident infectious diseases in the UKB, MGBB, and FinnGen cohorts, with incident infectious disease mortality in the BBJ cohort, and with COVID-19 severity in COVID-19-positive cases in the CUB, was assessed. A GWAS for expanded mCAs was then performed in the UKB to identify causal factors for expanded mCAs. Using the GWAS results, cell-specific functional enrichment analyses were performed using GenoSkyline-Plus, which combines epigenetic and transcriptomic annotations with GWAS summary statistics to estimate the relative contribution of cell-specific functional markers to the GWAS results. Additionally, to prioritize putative causal genes and pathways promoting the development of expanded mCAs, whole-blood TWAS was performed using UTMOST via GTExv8. **b,c**, The association of all expanded mCAs (cell fraction > 10%) (**b**) and expanded autosomal mCAs (cell fraction > 10%) (**c**) with age, stratified by sex for individuals in the UKB, MGBB, FinnGen and BBJ cohorts combined. Error bands are derived from binomial proportion 95% Cls. Plots by cohort and across other mCA groupings are available in Supplementary Figs. 8 and 9. BBJ, BioBank Japan; CUB, Columbia University Biobank; GTEx v8, Genotype-Tissue Expression Project version 8; GWAS, genome-wide association study; MGBB, Mass General Brigham Biobank; mCA, mosaic chromosomal alterations; MoChA, Mosaic Chromosomal Alterations software (https://github.com/freeseek/mocha); TWAS, transcriptome-wide association study; UKB, UK Biobank; UTMOST, Unified Test for Molecular Signatures.

indicate clonal hematopoiesis¹⁰⁻¹². mCAs are associated with aberrant leukocyte cell count and an increased risk for hematological malignancy and mortality¹⁰⁻¹⁸.

Although the relationship between mCAs and increased hematologic cancer risk is well-established^{10–12}, the impact of mCAs on age-related diminishment of immune function is poorly understood. We propose that mCAs increase the risk of infection, given that mCAs are somatic variants that increase in abundance with age and are associated with alterations in leukocyte count. In this study, we harness DNA genotyping array intensity data and long-range chromosomal phase information inferred from 768,762 individuals across five biobanks to analyze the associations between expanded mCA clones (that is, mCAs present in at least 10% of peripheral leukocyte DNA indicative of clonal expansion) and diverse infections, including severe coronavirus disease 2019 (COVID-19) from severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection (Fig. 1a). To elucidate genetic risk factors for the development of expanded mCA clones, we performed a genome-wide association study (GWAS) of data from the UK Biobank and subsequent in silico cell-specific, transcriptomic, and pathway analyses.

Results

Population characteristics and mCA prevalence. Data from a total of 768,762 unrelated, multi-ethnic individuals from the UK Biobank (UKB) (n=444,199), Mass General Brigham Biobank (MGBB) (n=22,461), FinnGen cohort (n=175,690), BioBank Japan (BBJ) (n=125,541) and the Columbia University Biobank (CUB) (n=871) who passed genotype and mCA quality control criteria (Supplementary Figs. 1–7) were analyzed (Supplementary Table 1). The mCA calls from the UKB and BBJ are taken from

studies that have been performed previously^{10,11}, while the Mosaic Chromosomal Alterations (MoChA) pipeline (https://github.com/ freeseek/mocha) was used to detect mCAs in the MGBB, FinnGen, and CUB cohorts (Extended Data Fig. 1) from genome-wide genotyping of blood DNA. For the UKB participants, the mean age at DNA collection was 57 (s.d. 8) years, 204,579 (46.1%) were male, 188,875 (45.0%) were prior or current smokers, and 66,551 (15.0%) had a history of solid cancer. In the MGBB participants, the mean age was 55 (s.d. 17) years, 10,306 (45.9%) were male, 9,094 (40.5%) were prior or current smokers, and 6,080 (27.1%) had a history of solid cancer. In the FinnGen participants, the mean age was 53 (s.d. 18) years, 71,000 (40.4%) were male, 42.7% were prior or current smokers (when smoking status was available) and 31,855 (18.1%) had a history of solid cancer. In the BBJ participants, the mean age was 65 (s.d. 12) years, 72,186 (57.5%) were male, and 66,913 (53.3%) were prior or current smokers, and 25,987 (20.7%) had a history of solid cancer. In the CUB participants, the mean age was 62.3 (s.d. 17.9) years, 480 (55.1%) were male, and 221 (25.4%) had a history of solid cancer (Supplementary Table 1).

In the UKB cohort, of 444,199 unrelated individuals without a known history of hematologic malignancy, 66,011 (14.9%) carried an mCA (15,350 autosomal) and 12,398 (3.2%) carried an expanded mCA clone, defined as an mCA mutation present in at least 10% of peripheral leukocytes (2,985 autosomal) (Supplementary Table 2). Although most of the carriers had only one mCA, 6% of individuals carried between 2 and 22 non-overlapping mCAs (Supplementary Fig. 7). In the MGBB cohort, of 22,461 unrelated individuals without a history of hematologic cancer, 3,784 (16.8%) carried an mCA (1,025 autosomal) and 1,026 (5.2%) carried an expanded mCA clone (337 autosomal). In the FinnGen cohort, of 175,690 individuals without a history of hematologic cancer, 22,040 (12.5%) carried an mCA (3,164 autosomal) and 9,558 (5.9%) carried an expanded mCA clone (1,620 autosomal). In the BBJ cohort, of 125,541 individuals without a history of hematologic cancer, only autosomal mCAs were available, with 20,440 carriers (16.3%), and 1,676 (1.3%) who carried an expanded clone. In the CUB COVID-19 cohort, of 871 individuals without a history of hematologic cancer, 258 (29.6%) carried an mCA (168 autosomal) and 177 (20.3%) carried an expanded mCA clone (128 autosomal) (Supplementary Table 2).

Consistent with previous reports, the prevalence of mCAs increased with age and they were more common in men (Supplementary Figs. 8 and 9 and Supplementary Table 3). Across the UKB, MGBB, FinnGen and BBJ cohorts combined, the prevalence of expanded mCAs was 0.5% in individuals aged <40 years, 1.2% in individuals aged 40–60 years, 7.8% in individuals aged 60–80 years, and 26.5% in those aged >80 years (Fig. 1b), the majority of which is due to the loss of the X chromosome (chrX) in female individuals (Supplementary Fig. 8). The prevalence of expanded autosomal mCAs was 0.27% for individuals aged <40 years, 0.52% for those aged 40–60 years, 1.5% for those aged 60–80 years, and 4.6% for those aged >80 years (Fig. 1c).

Association of mCAs with hematologic traits. We observed a striking association of mCA cell fraction with aberrant cell blood counts in blood samples acquired at the same visit as blood for genotyping (Fig. 2a,b). Increased mCA cell fraction was associated with overall increased white blood cell count, with general consistency across the cell differential components, and inflections at around a cell fraction of 0.1 (Fig. 2b). The strongest association across all mCA groupings (autosomal, chrX, chrY) with blood counts was the association between expanded autosomal mCAs and increased lymphocyte count at enrollment (β =0.40 s.d. or 0.25 × 10⁹ cellsl⁻¹; 95% confidence interval (CI)=0.36-0.44 s.d.; *P*=4.2×10⁻⁸⁴) (Fig. 2a and Supplementary Fig. 10).

Similarly, incident hematologic cancer risk was also strongly dependent on cell fraction (Fig. 2c). We reproduced the associations of mCAs with hematologic cancers that had previously been identified in the UKB data^{11,12}. We found that expanded autosomal mCAs with cell fraction >10% were most strongly associated with incident hematologic cancer (Fig. 2d), with the strongest association being for incident chronic lymphocytic leukemia (CLL) (hazard ratio (HR) 120.48; 95% CI=92.53–156.86; $P=2.2\times10^{-277}$), although an association with polycythemia vera (HR 32.56; 95% CI=22.81–46.48; $P=6.0\times10^{-82}$) and with myeloid leukemia (HR 11.82; 95% CI=7.29–19.18; $P=1.4\times10^{-23}$) was also present (Fig. 2d). In comparison, the associations of chrX and chrY mCAs with CLL were considerably weaker (chrX: HR 27.40; 95% CI=6.58–114.16; $P=5.5\times10^{-6}$; chrY: HR 1.91; 95% CI=0.96–3.80; P=0.064) (Fig. 2d).

Associations with diverse infections. Across the genome, the presence of any mCA was associated with diverse incident infections (defined in Supplementary Tables 4 and 5) (HR 1.06; 95% CI = 1.04-1.09; $P = 8.6 \times 10^{-8}$) (Supplementary Fig. 11), independent of age, age², sex, smoking status and the first ten principal components of ancestry in the combined UKB, MGBB and FinnGen meta-analysis. The dependence of this association on mCA cell fraction is further demonstrated in Fig. 3a,b, which shows an increase in the proportion of incident infection cases and incident sepsis cases with cell fraction, with greater slopes observed at a cell fraction of >10%. Accordingly, the associations across diverse infections were stronger for expanded mCA clones (HR 1.12; 95% CI=1.07-1.17; $P = 6.3 \times 10^{-7}$) (Fig. 3c). Furthermore, of the expanded mCA clones, the strongest association was observed for expanded autosomal mCAs (HR 1.25; 95% CI=1.15-1.36; $P=1.8 \times 10^{-7}$) (Fig. 3c). To account for multiple hypothesis-testing, expanded autosomal mCAs were significantly associated with sepsis (HR 2.68; 95% CI=2.25-3.19; $P=3.1\times10^{-28}$), respiratory system infections (HR 1.36; 95% CI=1.24-1.50; $P=3.8\times10^{-10}$), digestive system infections (HR 1.51; 95% CI = 1.32-1.73; $P = 2.2 \times 10^{-9}$) and genitourinary system infections (HR 1.25; 95% CI = 1.11-1.41; $P = 3.7 \times 10^{-4}$) (Fig. 3c). The specific expanded autosomal mCAs implicated for infection were diverse in nature (across all chromosomes, of different sizes), and included a mix of copy number gain, loss, and CNN-LOH mutations (Extended Data Fig. 2). Further associations across 20 specific infectious disease subcategories are enumerated in Extended Data Fig. 3. For sex chromosome mCAs, none of the incident infections achieved statistical significance (that is, P < 0.005) in a meta-analysis across the three cohorts; however, there was a trend towards an association with respiratory infections (expanded chrX: HR 1.45; 95% CI = 1.11–1.90; P = 0.0068; expanded chrY: HR 1.09; 95% CI = 1.03-1.16; P = 0.005) (Extended Data Fig. 4).

Risks for incident fatal infections were assessed in the BBJ cohort given that non-fatal incident infectious disease events are currently unavailable for BBJ. For individuals without any cancer history in the BBJ cohort, autosomal mCAs had nominal associations with fatal incident infections (HR 1.12; 95% CI=1.0-1.2; P=0.04), with expanded autosomal mCAs being associated with incident sepsis mortality (HR 2.04; 95% CI=1.04–4.16; P=0.05) (Supplementary Table 6 and Extended Data Fig. 5), as well as with pneumonia history (odds ratio (OR) 1.40; 95% CI=1.12–1.53; P=0.00080).

In a sensitivity analysis of the association of expanded autosomal mCAs and incident sepsis, the association was consistently significant across different age groups (Supplementary Fig. 12), and it was additionally independent of a 25-factor smoking covariate¹⁷, body mass index, type 2 diabetes mellitus, leukocyte count, lymphocyte count and lymphocyte percentage (Supplementary Table 7).

Stratified analyses indicated that expanded autosomal mCAs in individuals with cancer prior to infection (either any solid tumors or hematologic malignancy after the time of blood draw for genotyping) conferred a stronger association with sepsis (HR 2.79;

Fig. 2 | Associations of mCAs with hematologic traits. **a**, Linear regression of the association between blood counts and expanded mCAs. Associations are adjusted for age, age², sex, smoking status and principal components of ancestry. Error bars show the 95% CI for estimates, and the Bonferroni correction was used to determine the level of statistical significance. **b**, The relationship of mCA cell fraction with blood counts (in units of 10° cells I⁻¹) in the UKB in individuals without prevalent hematologic cancer at the time of blood draw for genotyping and cell count measurement. The dotted horizontal lines reflect the mean blood count for individuals without an mCA. The dotted vertical lines at the cell fraction of 0.10 represent the cut-off for the definition of expanded mCA. Individuals with known hematologic cancer at the time of or prior to blood draw for genotyping were excluded. Error bands reflect the standard error of a generalized additive model with integrated smoothness fit to the data. **c**, Association of expanded mCA categories (with cell fraction > 10%) with incident cancer in the UKB. Analyses are adjusted for age, age², sex, smoking status and principal components of ancestry. Individuals with a history of hematologic cancer at enrollment were removed from the analysis. Error bands are derived from binomial proportion standard errors. **d**, Assessment of the association of the expanded mCA categories (with cell fraction > 10%) with incident cancer in the UKB, using Cox proportional hazards modeling, with time-on-study as the underlying timescale. Analyses are adjusted for age, age², sex, smoking status and principal components of ancestry. Error bars show the 95% CI for estimates, and the Bonferroni correction was used to determine the level of statistical significance. Individuals with a history of hematologic cancer at enrollment were removed from analysis. AML, acute myeloid leukemia; MPN, myeloproliferative neoplasm; RBC, red blood cell; WBC, white blood cell.

95% CI=2.30–3.38; $P=9.7 \times 10^{-26}$) and respiratory system infections (HR 1.60; 95% CI=1.40–1.82; $P=6.1 \times 10^{-12}$) compared with individuals without a prior cancer history (sepsis: HR 1.25; 95% CI=0.80–1.95; P=0.33, $P_{\text{interaction}}=0.001$; respiratory system infections: HR 1.16; 95% CI=1.00–1.34; P=0.045, $P_{\text{interaction}}=0.001$) (Fig. 4 and Supplementary Figs. 13–15). This interaction was driven by

prevalent solid cancer, not hematologic cancer, after DNA acquisition for mCA genotyping (Supplementary Table 8). Further multivariable adjustment indicated that incident sepsis and infection were independent of chemotherapy, neutropenia, aplastic anemia, decreased white blood cell count, bone marrow or stem cell transplant, and radiation effects prior to infection (with these phenotypes

Fig. 3 | Association of expanded mCAs with incident infections. a,b, The proportion of individuals in the UKB with any incident infection or sepsis, according to cell fraction, for all mCAs (**a**) and autosomal mCAs (**b**), in individuals without prevalent hematologic cancer at the time of blood draw for genotyping. The dotted vertical lines at a cell fraction of 0.10 represent the cut-off for the definition of expanded mCAs. Error bands are derived from binomial proportion standard errors. **c**, The association of any expanded mCA, and separately, expanded autosomal mCAs, with incident infections across individuals in the UKB, MGBB and FinnGen cohorts, using Cox proportional hazards modeling with the underlying timescale of time-on-study. Analyses are adjusted for age, age², sex, smoking status and principal components 1-10 of ancestry. Error bars show the 95% CI for estimates, and the Bonferroni correction was used to determine the level of statistical significance. Individuals with prevalent hematologic cancer were excluded from analysis. Association analyses for other groupings of mCAs (including across all mCAs regardless of cell fraction, as well as chrX and chrY mCAs) are provided in Supplementary Figs. 11 and 12. BBJ, BioBank Japan; mCA, mosaic chromosomal alterations; MGBB, Mass General Brigham Biobank; UKB, UK Biobank.

defined using International Classification of Diseases tenth revision (ICD-10) and ICD-9 phecode groupings¹⁹) (Supplementary Table 9). We also explored the time difference between cancer diagnosis and specific infections to characterize the potential influence of expanded mCA. Univariable analyses showed that expanded mCA

carriers tend to have a twofold higher incidence of post-cancer diagnosis septicemia and pneumonia, and that the difference in incidence rate was more prominent in infections occurring >3 years after the cancer diagnosis (Supplementary Table 10 and Supplementary Fig. 16). Besides cancer patients, we also calculated the univariable

Fig. 4 | Association of expanded autosomal mCAs and incident infections, stratified by antecedent cancer history. a, The association of expanded autosomal mCAs with incident infections across individuals with and without a cancer history before their incident infection, in a meta-analysis of the UKB, MGBB and FinnGen cohorts combined (cohort-specific analyses are available in Supplementary Fig. 14), assuming a fixed effect. Error bars show the 95% CI for estimates, and the Bonferroni correction was used to determine the level of statistical significance. Individuals with known hematologic cancer at the time of or prior to blood draw for genotyping were excluded. Analyses are adjusted for age, age², sex, smoking status and principal components of ancestry. **b**, Cumulative incidence curves for various infections in the UKB. (Results from the MGBB and FinnGen are available in Supplementary Fig. 16.) Red, mCA positive and cancer positive; purple, mCA negative and cancer positive; blue, mCA positive and cancer negative; green, mCA negative and cancer negative. Individuals with known hematologic cancer at the time of or prior to blood draw for genotyping were excluded.

association between expanded mCA and diseases in the general public. On average, if we followed individuals without documented cancer, sepsis, or pneumonia history in the UKB for 1,000 person-years after expanded mCA detection, we would observe that 36 individuals develop incident cancer (5 cases of which would be hematological cancer), 14 individuals develop incident pneumonia, and 8 develop incident sepsis (Extended Data Fig. 6). Association with COVID-19 severity. Across 719 cases of hospitalization for COVID-19 in the UKB, 44 individuals (6%) carried an expanded mCA clone at the time of enrollment (in 2010), compared with 3% of 337,877 controls. Adjusting for age, age², sex, prior or current smoking status and principal components of ancestry, expanded mCAs were associated with COVID-19 hospitalizations (OR 1.59; 95% CI=1.13–2.25; P=0.0082), with higher effect

NATURE MEDICINE

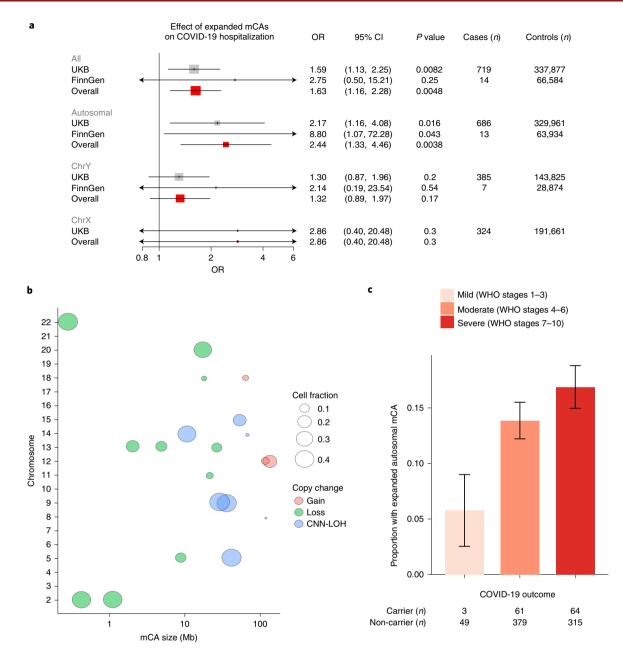

Fig. 5 | Association of expanded mCAs with COVID-19 severity. **a**, The association of expanded mCAs with COVID-19 hospitalization across the UKB and FinnGen cohorts, determined by logistic regression. Error bars show the 95% CI for estimates, and the Bonferroni correction was used to determine the level of statistical significance. Individuals with known hematologic cancer at the time of or prior to blood draw for genotyping were excluded. Analyses are adjusted for age, age², sex, ever smoking status and the principal components of ancestry. **b**, Visual representation of the diverse range of expanded autosomal mCAs detected across the genome in individuals hospitalized with COVID-19 in the UKB cohort. Each point represents one mCA carried by a hospitalized individual with COVID-19. **c**. Proportion of expanded autosomal mCAs in each category of COVID-19 outcomes for the CUB COVID-19 cohort, defined using the WHO COVID-19 scale (n = 871 participants). The binomial proportion 95% CI sare shown. In the CUB cohort, the OR of the adjusted association between expanded autosomal mCAs and these ordinal COVID-19 outcomes, evaluated using ordinal regression, is 1.52 (95% CI = 1.04-2.21; P = 0.031, two-tailed). The summary statistics for the covariates included in the adjusted model for the CUB cohort are listed in Supplementary Table 11. CNN-LOH, copy number neutral loss of heterozygosity; CUB, Columbia University Biobank; MGBB, Mass General Brigham Biobank; UKB, UK Biobank; WHO, World Health Organization.

estimates conferred by expanded autosomal mCAs (OR 2.17; 95% CI = 1.16–4.08; P=0.016) (Fig. 5a). Analyses in the FinnGen cohort showed evidence of independent replication. The meta-analyzed associations across the UKB and FinnGen of expanded autosomal mCAs on COVID-19 hospitalization were OR 2.44 (95% CI 1.33 to 4.46; P=0.0038). In the UKB, further sensitivity analysis was performed; the associations persisted with additional adjustment for

normalized Townsend deprivation index, normalized body mass index, type 2 diabetes mellitus, hypertension, coronary artery disease, and any cancer, asthma, and chronic obstructive pulmonary disease (Extended Data Fig. 7a). Additionally, similar associations were observed in the UKB when comparing COVID-19 hospitalization with tested negative controls, COVID-19 positive with all participants from English provinces, and COVID-19 positive with tested negative controls (Extended Data Fig. 7b). Similar to the diverse nature of mCA clones observed in cases of incident infection, specific mCA clones carried by individuals hospitalized with COVID-19 were also diverse in nature: across multiple chromosomes, a wide range of sizes, and across copy number gain, loss, and CNN-LOH (Fig. 5b). Similar associations of expanded mCAs with COVID-19 were also observed for incident pneumonia in the UKB (Extended Data Fig. 7c).

We next identified 871 patients with COVID-19 from the CUB and classified them into mutually exclusive ordinal categories based on COVID-19 outcomes and the World Health Organization (WHO) COVID-19 progression scales: mild cases (n = 52), COVID-19 infection not requiring hospitalization (WHO stages 1-3); moderate cases (n = 440), COVID-19 infection requiring hospitalization but without intubation or death (WHO stages 4-6); and severe cases (n=379), respiratory failure due to COVID-19 requiring endotracheal intubation and mechanical ventilation (n = 140; WHO stages 7–9) or death from COVID-19 (n = 239; WHO stage 10). Individuals with prevalent hematologic cancer were excluded from analyses as before. Expanded autosomal mCAs were detected in 5.8% of patients with mild cases, in 13.9% of patients with moderate cases, and in 16.9% of patients with severe cases (Fig. 5c). Expanded autosomal mCAs were associated with these ordinal COVID-19 outcomes with an OR of 1.52 (95% CI = 1.04-2.21; P=0.031), adjusted for age, sex and self-reported ancestry. Summary statistics for the multivariate logistic regression are listed in Supplementary Table 11. This association was also independent of the status of any other prevalent cancers, as validated by a sensitivity analysis that includes adjustment for any cancer diagnosis (Supplementary Table 12).

Germline genetic predisposition to expanded mCAs. To further elucidate causal factors for expanded mCA clones, we performed a GWAS in the UKB cohort. We identified 63 independent genome-wide significant loci ($r^2 < 0.1$ across 1 megabase (Mb) windows of the genome) (Fig. 6a and Supplementary Table 13). Across the 63 germline variants, significant correlation was seen between different mCA categories (Extended Data Fig. 8), suggesting the presence of shared germline genetic variants predisposing to mCAs across the genome. Follow-up analyses using an additive polygenic risk score consisting of 156 independent genome-wide significant variants associated with mosaic loss of chromosome Y (mLOY) from male participants from a prior study in the UKB²⁰, found significant associations with expanded autosomal mCAs and expanded chrX mCAs in female participants, further highlighting the shared germline contributors towards mCAs across the genome (Extended Data Fig. 9). The association of the 156 previously identified independent genome-wide significant variants associated with mLOY²⁰ with the expanded chrY mCA categories in the UKB cohort shows that the two are highly correlated ($r_p = 0.91$; $P = 3.80 \times 10^{-57}$), with 1.87-fold higher effect estimates conferred on expanded chrY mCAs compared with all mLOY variants²⁰ (Supplementary Fig. 17). Additionally, a strong correlation is seen between germline variants associated with mLOY and their associations with expanded chrX mCAs, expanded autosomal mCAs, and all expanded mCAs (Supplementary Fig. 17). Further analysis of the TP53 variant rs78378222-G identified a particularly strong effect on expanded chrY mCAs (OR 2.03; 95% CI = 1.79-2.31; $P = 1.33 \times 10^{-27}$) in addition to all chrY mCAs (OR 1.79; 95% CI = 1.66 - 1.92; $P = 8.81 \times 10^{-53}$), with the chrY mCA effect being very similar to that previously reported by Thompson et al.²⁰ (Supplementary Table 14). The TP53 variant rs78378222-G was also associated with expanded autosomal mCAs (OR 1.51; 95% CI=1.21-1.88; P=0.00031) and expanded chrX mCAs (OR 2.26; 95% CI=1.30-3.92; P=0.0038). The autosomal mCAs carried by individuals with rs78378222-G were diverse in size, copy change and location in the genome (Supplementary Fig. 18). A transcriptome-wide association study (TWAS) combining the expanded mCA GWAS results with Genotype-Tissue Expression project version 8 (GTExv8; ref. 21) whole-blood expression quantitative trait loci using UTMOST (unified test for molecular signatures)²² prioritized 62 genes ($P < 3.2 \times 10^{-6}$) promoting expanded mCA development (Fig. 6b and Supplementary Table 15). Although gene enrichment analyses with the Elsevier Pathway Collection did not identify significantly associated pathways after multiple testing correction, the top pathways were linked to DNA damage repair and lymphoid processes (Extended Data Fig. 10a, Supplementary Table 16). The corresponding GWAS LocusZoom plots for some of these immune-related genes are shown in Extended Data Fig. 10b. To prioritize the tissues that were most strongly implicated by these loci, tissue enrichment analyses using GenoSkyline-Plus were performed. Significant enrichment was identified in immune-specific epigenetic and transcriptomic functional regions of the genome $(P=7.1\times10^{-9})$ (Fig. 6c). Further stratification of the immune category identified specific enrichment for CD4+ T cells (P=0.00098) (Fig. 6d).

Discussion

Across five geographically distinct biobanks of data on 768,762 individuals without known hematologic malignancy, clonal hematopoiesis, represented by expanded mCAs, is increasingly prevalent with age but is not readily detectable by conventional medical blood tests. In addition to strongly predicting the future risk of hematologic malignancy, expanded mCAs are also associated with the risk for diverse incident infections, particularly sepsis and respiratory infections. These findings are robust across age, sex and tobacco smoking, and are strongest for those who develop cancer. Consistent with these observations, expanded mCAs are also associated with increased odds for COVID-19 hospitalization.

These results support several conclusions. First, mCA-driven clonal hematopoiesis is a potential risk factor for infection. Recent work has shown that clonal hematopoiesis with myeloid malignancy driver mutations, also referred to as 'clonal hematopoiesis of indeterminate potential', predisposes to myeloid malignancy and coronary artery disease²³⁻²⁷. Meanwhile, clonal hematopoiesis with larger chromosomal alterations (that is, mCAs) predisposes primarily to lymphoid malignancy but not coronary artery disease^{10-12,15,16}. Our observations suggest that clonal hematopoiesis (defined as the presence of mCAs) is a risk factor for infection. Given that the relationship between mCAs and infection risk was not substantially attenuated when adjusting for leukocyte or lymphocyte counts at the baseline visit, the impact of mCAs on infection risk possibly acts through mechanisms independent of the impact of clonal hematopoiesis on cell counts. As an example, given that mCAs alter gene dosage (for example, via duplications and deletions) and remove allelic heterogeneity (for example, CNN-LOH events) in leukocytes, potential impacts on the differentiation, function and survival of leukocytes are mechanisms that could lead to altered infection risk. Our germline analyses specifically implicate lymphoid tissues. In particular, many of the mCA susceptibility loci are the same as those found in CLL, a condition in which lymphocyte differentiation and function are altered, promoting infection risk²⁸⁻³¹. Therefore, molecular changes in leukocytes that promote clonal expansion may occur at the expense of reduced ability to combat infection.

Second, the infectious disease risk associated with mCAs is exacerbated in the setting of cancer. It is well-established that mCAs in blood-derived DNA increase the risk for hematologic cancer¹⁰⁻¹². Furthermore, recent evidence suggests an association between mCAs detected in blood-derived DNA and an increased risk of select solid tumor^{14,17,32}. Our analysis identified an interaction between mCAs and prior cancer diagnosis that amplified the sepsis and pneumonia risk. Importantly, this interaction was restricted to individuals with solid cancers, not antecedent blood cancer. Although this observation could be partially due to synergistic

ARTICLES

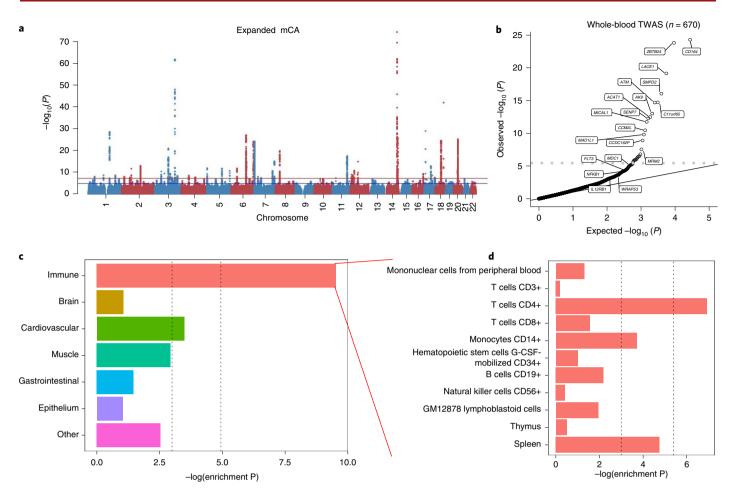

Fig. 6 | Inherited risk factors for expanded mCAs: GWAS, TWAS and cell-type enrichment. a, GWAS for expanded mCA identified 63 independent loci. **b**, Quantile-quantile plot of the whole-blood TWAS of the expanded mCA GWAS using 670 samples from GTExv8, showing significant enrichment across 62 genes. The horizontal dotted line reflects the Bonferroni-adjusted *P* value for significance. Genes with $P < 5 \times 10^{-8}$ in the TWAS or those important in the pathway enrichment analyses from Extended Data Fig. 10 are labeled. **c**, Cell-type enrichment results from the expanded mCA GWAS across immune, brain, cardiovascular, muscle, gastrointestinal, epithelium, and other tissues, as annotated using GenoSkyline-Plus annotations. **d**, A zoom-in of **c** to show the stratified enrichment by specific categories of immune cells and tissues. In **c** and **d**, the vertical dashed lines indicate P = 0.05 for suggestive enrichment. and the Bonferroni-adjusted *P*-value for significant enrichment.

immunosuppressive side-effects of cancer therapies³³, the observed associations persisted despite adjustment for many of these treatments. Alternatively, abnormal regulation of immune inflammatory pathways that release cytokines and inflammatory cells may create chronic states of inflammation in individuals with mCAs^{34,35}. Based on our analysis, carriers of autosomal mCA are at an increased risk for sepsis (2.7-fold), pneumonia (1.8-fold), respiratory system infections (1.4-fold), digestive system infections (1.5-fold) and genitourinary system infections (1.3-fold), and these effects are more prominent in cancer patients. Surveillance for expanded mCA clones, particularly for those who develop solid cancer, may help identify individuals at high risk for infection who could benefit from targeted interventions.

Third, our findings could have particular relevance for the ongoing COVID-19 pandemic. We observed that mCAs are associated with elevated risk for COVID-19 hospitalization, with a greater than twofold risk linked to expanded autosomal mCAs. Maladaptive immune responses, particularly in leukocytes, increase the risk for severe COVID-19 infections^{36–39}. Awareness of the COVID-19 risk associated with mCAs may help with the prioritization of prophylactic treatments. However, the question of whether immune response to current vaccination approaches is altered in the context of mCAs deserves further study. Last, the mCA germline genetic associations identified in the present study replicate many of those previously identified^{10,11,20} and additionally suggest a common heritable basis across mCA classes, which may inform therapeutic targets. Genetic variants that influence the risk of autosomal mCAs also influence the risk of chrX mCAs in female individuals and that of chrY mCAs in male individuals. Furthermore, previously published genetic variants associated with mLOY²⁰ also influence the risk of autosomal mCAs and chrX mCAs in female individuals. These loci may support putative therapeutic targets that may decrease the risk of mCA development, the rate of mCA clonal expansion, or the risk of progression of mCAs to clinical outcomes.

This analysis of mCAs and infection had some limitations. First, our study measures mCAs only at one time point for each participant. Although our sampled mCA time point is probably correlated with clonal hematopoiesis at the time of infection, clonal hematopoiesis dynamically changes over time, potentially leading to differences in cellular fraction or additional undetected events that were acquired prior to infection. Second, we cannot rule out the possibility of undiagnosed hematologic malignancy in individuals with mCAs with only blood DNA. However, given the observed prevalence of mCAs (4% by age 60 years) in individuals without diagnosed hematologic malignancy and the general scarcity of

hematologic malignancy in the general population, we anticipate that undiagnosed hematologic malignancy at DNA acquisition will be uncommon. Third, despite the robust adjustment and sensitivity analyses performed in the statistical analysis, including adjustment for cancer subtype, chemotherapy, bone marrow transplant, radiation, and other features associated with poor cancer prognosis (neutropenia, aplastic anemia, decreased white blood cell count), we cannot completely rule out the impact of residual confounding from unknown or unmeasured sources on the results. Here, consistency across cohorts and infection types, and biologic plausibility mitigate this possibility, and the empiric association of mCAs with incident infection may enable improved clinical risk prediction in patient populations as further scientific work is performed to understand the biological mechanisms by which mCAs influence the immune system. Last, further causal inference analyses using methods such as Mendelian randomization are limited by the low heritability of autosomal mCAs¹¹ and the low heritability of infectious diseases^{40,41}. However, defects in humoral, cell-mediated and innate immunity have been linked to CLL²⁸⁻³¹. Whether all of these or specific aspects of immunity are altered for this pre-CLL condition requires further study.

In conclusion, we report evidence for increased susceptibility to a spectrum of infectious diseases in individuals carrying autosomal mCAs in a detectable fraction of leukocytes. The impacts of mCA on infection risk are systemic, with increased susceptibility to infection observed for a variety of organ systems, including severe COVID-19 presentations.

Methods

Study samples. The UKB, a population-based cohort of approximately 500,000 participants recruited from 2006 to 2010, has existing genomic and longitudinal phenotypic data⁴². Baseline assessments were conducted at 22 assessment centers across the United Kingdom, with sample collections including blood-derived DNA. Of 488,377 genotyped individuals, we analyzed 445,101 participants who consented to genetic analyses and who passed sample quality control criteria for mCA calling, had genotypic-phenotypic sex concordance, no first- or second-degree relatives (random exclusion of one from each pair), and no prevalent hematologic cancer at the time of blood draw. Genome-wide genotyping of blood-derived DNA was performed by UKB using two genotyping arrays sharing 95% of marker content: Applied Biosystems UK BiLEVE Axiom Array (807,411 markers in 49,950 participants) and Applied Biosystems UK Biobank Axiom Array (825,927 markers in 438,427 participants), both by Affymetrix⁴². Secondary use of the data was approved by the Massachusetts General Hospital Institutional Review Board (protocol 2013P001840) and was facilitated through UKB applications 7089 and 21552.

The MGBB contains genotypic and clinical data from >105,000 patients who consented to broad-based research across seven regional hospitals⁴³. Baseline phenotypes were ascertained from the electronic medical record and from surveys on lifestyle, environment, and family history. Of the approximately 36,000 genotyped individuals, 27,778 samples had available probe raw intensity data (IDAT) files for mCA calling. Blood-derived DNA samples were genotyped using three versions of the Multi-Ethnic Genotyping Array (MEGA) Single-Nucleotide Polymorphism (SNP) array offered by Illumina. Secondary use of the data was approved by the Massachusetts General Hospital Institutional Review Board (protocol 2020P000904).

The FinnGen project (https://www.finngen.fi/en), launched in 2017, covers the whole of Finland and aims to improve the health of people around the world through genetic studies. The latest released version (R6) contains genotypic, demographic and extensive health information (for example, a national inpatient register since 1969 and a national outpatient register since 1998, a cancer register since 1953, and a drug reimbursement register since 1964) from 269,077 Finnish individuals. Blood-derived DNA samples were genotyped using two versions of FinnGen Thermo Fisher Axiom custom array (https://www.finngen.fi/en/ researchers/genotyping) provided by the Thermo Fisher genotyping service facility.

The BBJ is a hospital-based registry that collected clinical, DNA, and serum samples from approximately 200,000 consenting patients with one or more of 47 target diseases at a total of 66 hospitals between 2003 and 2007 (ref. ⁴⁴). Blood DNA was genotyped in three batches using different arrays or a set of arrays, namely: (1) a combination of Illumina Infinium Omni Express and Human Exome; (2) Infinium Omni Express Exome v.1.2; which capture very similar SNPs. These analyses were approved by the ethics committees of RIKEN Center for Integrative Medical Sciences and the Institute of Medical Sciences, The University of Tokyo.

The CUB COVID-19 cohort includes multi-ethnic patients with COVID-19 who were treated at the Columbia University Irving Medical Center (CUIMC) and who underwent SNP genotyping on the Illumina Infinium Global Diversity Array. All patients in the cohort had a polymerase chain reaction-confirmed SARS-CoV-2 infection. All patients who had a blood draw at CUIMC after their positive polymerase chain reaction test were recruited regardless of hospitalization status. These patients were recruited to the CUB between March and May 2020, at the peak of the first wave of the New York City pandemic, thus only a small fraction of the cohort was not hospitalized. The CUB COVID-19 studies are reviewed and approved by the Columbia University Medical Center Institutional Review Board. A subset of patients was included under a public health crisis institutional review board waiver of consent specifically for COVID-19 studies if patients were deceased, not able to consent, or if the study team was unable to contact them as per the Columbia Institutional Review Board protocols AAAS9552 and AAAS7370. The primary analysis involved 871 patients and excluded individuals who had hematological malignancies. This cohort (n = 871) was composed of 480 male participants and 391 female participants; the average age was 62 years (range, 7-101 years); 52% of the participants self-reported as being Hispanic or Latinx, 14% self-reported as being Black or African American, 11% self-reported as being white or European and 23% self-reported as other or unknown. All COVID-19-positive patients were classified into mutually exclusive ordinal outcome categories as defined by the WHO: mild cases (n = 52), COVID-19 infection not requiring hospitalization (WHO stages 1–3); moderate cases (n = 440), COVID-19 infection requiring hospitalization but without intubation or death (WHO stages 4–6); and severe cases (n = 379), respiratory failure due to COVID-19 requiring endotracheal intubation and mechanical ventilation (n = 140; WHO stages 7-9) or death from COVID-19 (n = 239; WHO stage 10).

Mosaic chromosomal alteration detection. The detection of mCAs in the UKB has been described previously^{11,12}. In brief, genotype intensities were transformed to log₂ R ratio (LRR) and B-allele frequency (BAF) values to estimate total and relative allelic intensities, respectively. Re-phasing was performed using Eagle2 (ref. ⁴⁵), and mCA calling was performed by leveraging long-range phase information to search for allelic imbalances between maternal and paternal

allelic fractions across contiguous genomic segments. Constitutional duplications and low-quality calls were filtered out and cell fraction was estimated as previously described¹². UKB mCA calls were obtained from dataset Return 2062 generated from UKB application 19808.

Detection of mCAs in the MGBB was performed starting from raw IDAT files from the Illumina MEGA. Genotype clustering was performed using the Illumina GenCall algorithm. The resulting GTC genotype files were converted to VCF files using the bcftools gtc2vcf plugin (https://github.com/freeseek/gtc2vcf). Genotype phasing across the whole cohort was performed using SHAPEIT4 (ref. 4) in windows of a maximum of 20 cM, with an overlap of 2 cM between consecutive windows. Phased genotypes were ligated across overlapping windows using bcftools concat (https://github.com/samtools/bcftools). mCA detection in the MGBB was performed using MoChA1,2 (https://github.com/freeseek/mocha). A pipeline to execute the whole workflow from raw files all the way to final mCA calls is available in WDL (workflow description language) format for the Cromwell execution engine46 as part of MoChA. We excluded 160 samples with phased BAF auto-correlation >0.05, which is indicative of contamination or of other potential sources of poor DNA quality, and 67 samples with phenotype-genotype sex discordance (Supplementary Fig. 1). We removed probable germline copy number polymorphisms (lod_baf_phase <20 for autosomal variants and lod_baf_phase <5 for sex chromosome variants), constitutional or inborn duplications (mCAs of <2 Mb with relative coverage >2.25, and mCAs of 2–10 Mb with relative coverage >2.4) and deletions (filtering out mCAs with relative coverage <0.5) (Supplementary Fig. 2).

FinnGen blood samples are genotyped using two versions of the FinnGen Thermo Fisher Axiom custom array. The detection of mCAs in FinnGen was performed, starting from the genotype-intensity tables of 201,322 samples using the 'txt' mode of the MoChA WDL pipeline (https://github.com/freeseek/mocha). The input genotype-intensity tables for mCA detection were directly provided by the Thermo Fisher genotyping service, which performed genotype calling from the raw CEL files for each batch using the apt-probeset-genotype tool. Genotype phasing across the whole cohort was performed using SHAPEIT4 in windows of a maximum of 20 cM, with 2 cM of overlap between consecutive windows. Phased genotypes were ligated across overlapping windows using bcftools concat (https:// github.com/samtools/bcftools). We excluded 215 samples with phased BAF auto-correlation >0.05, which is indicative of contamination or of other potential sources of poor DNA quality, and 83 samples with phenotype-genotype sex discordance (Supplementary Fig. 3). We removed probable germline copy number polymorphisms (lod_baf_phase <20 for autosomal variants and lod_baf_phase <5 for sex chromosome variants, and lod_baf_phase <10 unless they are larger than 5 Mb (or 10 Mb if they span the centromere)), constitutional or inborn duplications (0.5-5 Mb mCAs with relative coverage >2.5 and Bdev < 0.1, and 5-10 Mb mCAs with relative coverage >2.75) and deletions (filtering out mCAs with relative coverage <0.5) (Supplementary Fig. 4). After further removing firstor second-degree relatives, and individuals with any prevalent hematologic cancer history at the time of blood draw for genotyping, there were 175,690 samples remaining for analyses.

The detection of mCAs in the BBJ has been described previously¹⁰. In brief, genotyping intensity data were analyzed across variants shared between the three primary arrays, and were used to compute BAF and LRR values. Phasing was performed using the Eagle2 software. Mosaic events were called as previously described¹².

The CUB COVID-19 blood samples were genotyped using the Illumina Infinium Global Diversity Array. Detection of mCAs was performed starting from the probe raw IDAT files of 1,182 samples. The resulting raw intensity data were converted to VCF files using the bcftools gtc2vcf plugin (https://github.com/ freeseek/gtc2vcf). Genotype phasing was performed using Eagle2 over the entire cohort. After excluding samples with a call rate of <0.97 and further removing first- or second-degree relatives, the mCA calling was performed using the MoChA pipeline (https://github.com/freeseek/mocha). We excluded 133 samples with phased BAF auto-correlation >0.05, indicative of contamination or of other potential sources of poor DNA quality, and six samples with phenotype-genotype sex discordance (Supplementary Fig. 5). We removed probable germline copy number polymorphisms (lod_baf_phase <20 for autosomal variants and lod_baf_ phase <5 for sex chromosome variants), constitutional or inborn duplications (0-10 Mb mCAs with relative coverage >2.4) and deletions (filtering out mCAs with relative coverage <0.5) (Supplementary Fig. 6). We further excluded 32 individuals with any prevalent hematologic cancer history at the time of blood draw for genotyping and had 871 samples remaining for analyses.

Clinical outcomes. Definitions of infection outcomes are detailed in Supplementary Tables 4 and 5. In the UKB, the first reported occurrences over a median 8 year follow-up in category 2410 were used as categorized by the UKB, which maps primary care data, ICD-9 and ICD-10 codes from hospital inpatient data, ICD-10 codes in death register records, and self-reported medical conditions reported at the baseline, to ICD-10 codes. For each set of phenotypes grouped by organ system or by category, the time to first incident event after baseline examination in individuals free of prevalent history of each disease category was used. In the MGBB, electronic health record data were used to

ARTICLES

define incident ICD-10 codes grouped in the same fashion after DNA collection date over a median 3 year follow-up. In the FinnGen cohort, phenotypes were grouped together across ICD-8, ICD-9 and ICD-10 codes (Supplementary Table 2), with incident infections defined after DNA collection date over a median 3 year follow-up. In BBJ, analyses were performed using fatal incident events attributed to diverse infection outcomes in Supplementary Table 1, given that non-fatal incident events were not available. Additionally, analyses for pneumonia were performed using a history of pneumonia prior to genotyping, based on interviews and medical record reviews44. Cancer cases in the UKB were identified using the cancer register (category 100092) in combination with the inpatient ICD-10 registry (field identification numbers 41270 and 41280). Hematologic cancer cases in the UKB were identified using the cancer registry's field identification number 40011 (hematological cancer identified from biopsy), the field identification numbers 40005 and 40006 in combination with the ICD-10 code ranges C81-96 and D45-47, and the inpatient ICD-10 registry (field identification numbers 41270 and 41280, in combination with the ICD-10 code ranges C81-96 and D45-47). In the MGBB, cancer cases were identified using the ICD-10 code range C00-D49, and hematologic cancer cases were identified using the ICD-10 code ranges C81-96 and D45-47. Other clinical phenotypes defined in the UKB, MGBB, and FinnGen cohort are detailed in Supplementary Tables 17-19. Smoking status in the MGBB was defined using a combination of electronic health record data and survey data. Follow-up time was coded as the time from blood draw for genotyping to the event (development of incident phenotype) or, for controls, as the time from sample collection to either the censor date (31 October 2019) or the date of death if the patient died prior to the last censor. Smoking status in the FinnGen cohort was defined based on survey data. Follow-up time was coded as the time from blood draw for genotyping to the event (development of incident phenotype) or, for controls, as the time from sample collection to either the censor date (31 December 2019) or the date of death if the patient died prior to the last censor.

UKB COVID-19, from SARS-CoV-2 infection, phenotypes used in the present analysis were downloaded on 27 July 2020. SARS-CoV-2 infection was determined using polymerase chain reaction testing of nasopharyngeal, oropharyngeal or lower respiratory samples obtained between 16 March 2020 and 17 July 2020. Patients with COVID-19 requiring hospitalization were defined as any individual with at least one positive test who also had evidence for inpatient hospitalization (field identification number 40100). The controls included two sets: participants from UKB English recruitment centers who were not known to have COVID-19 (that is, individuals with negative or no known SARS-CoV-2 testing); or participants with a negative SARS-CoV-2 test. Individuals with COVID-19 of unknown or low severity (that is, individuals who had at least one positive SARS-CoV-2 test without a known hospitalization) were excluded from the primary analyses.

Replication was performed in the FinnGen cohort when SARS-CoV-2 infection was confirmed, either by polymerase chain reaction testing or by identification of antibodies in samples obtained between 2 March 2020 and 27 July 2020. Across both the UKB and FinnGen cohorts, individuals who died prior to 1 March 2020, and therefore were not at risk for COVID-19 infection, were excluded from COVID-19 analyses.

Statistical methods for infection associations. Analyses of the association of expanded mCAs with primary incident infection across the ten main infectious disease organ system categories (listed under 'organ system' in Supplementary Table 1) were performed using Cox proportional hazards models, adjusting for age, age², sex, ever smoking status and principal components 1-10 from the genotyping data. The age² term was added to account for potential quadratic associations between age and disease occurrence, given that the association between mCAs and age is also nonlinear. Time since DNA collection was used as the underlying timescale. The proportional hazards assumption was assessed using Schoenfeld residuals and was not rejected. Individuals with a history of hematological cancer prior to DNA collection were excluded. The threshold of significance used in the analyses of primary organ system infection was a two-sided Bonferroni threshold, P < 0.05/10 = 0.005, to account for multiple hypothesis-testing. Analyses of incident events were performed separately in each biobank using the survival package in R (version 3.5, R Foundation). Meta-analyses of the UKB, MGBB and FinnGen results were performed using a fixed-effects model from the meta package.

For the UKB COVID-19 analyses, logistic regression was performed to estimate the association between expanded mCAs and COVID-19 hospitalization using the aforementioned phenotype definition, adjusting for sex, age, age², smoking status and the first ten principal components from the genotyping data. As above, individuals with prevalent hematologic cancer were excluded from analyses. For the COVID-19 analyses, statistical significance was assigned using a two-sided *P* value of <0.05. Secondary multivariable models were additionally adjusted for normalized Townsend deprivation index⁴⁷, normalized body mass index at enrollment visit, and any prevalent or incident type 2 diabetes mellitus, hypertension, coronary artery disease, cancer, asthma and chronic obstructive pulmonary disease.

Further sensitivity analyses were performed to assess the associations between expanded autosomal mCAs and infection in the UKB. First, the associations of 20 incident infections with mCAs, across the ten broader organ system groups, were assessed using a Bonferroni threshold of significance (P < 0.05/20 = 0.0025).

Second, stratified cancer analyses were performed in individuals with antecedent cancer prior to their incident infection in both the UKB and MGBB, additionally stratifying for the same aforementioned covariates (age, age², sex, ever smoking status and the first ten principal components of genetic ancestry). Third, an interaction analysis was performed using an mCA×antecedent cancer term in the model to analyze the interaction between mCAs and antecedent cancer prior to incident infection. Fourth, for the incident sepsis association, four sets of covariates were added to the Cox proportional hazards model: (1) normalized body mass index and type 2 diabetes mellitus, (2) any antecedent cancer prior to incident infection, (3) adjustment for a more comprehensive 25-factor smoking phenotype17, and (4) adjustment for normalized leukocyte count, lymphocyte count and lymphocyte percentage at baseline visit. Fifth, we evaluated the association of expanded autosomal mCAs with incident sepsis and pneumonia in subgroups of individuals with cancer prior to infection (that is, those with prevalent solid cancer, incident hematologic cancer, and incident solid cancer prior to infection), in models adjusted for age, age², sex, ever smoking status and the first ten principal components of genetic ancestry. Last, we further evaluated the association of expanded autosomal mCAs with incident pneumonia and sepsis in separate models adjusted for different predictors of cancer morbidity including chemotherapy, neutropenia, aplastic anemia, decreased white blood cell count, bone marrow or stem cell transplant, and radiation effects prior to infection (with these phenotypes defined using the Vanderbilt ICD-10 and ICD-9 phecode groupings¹⁹), in the same aforementioned models adjusted for age, age², sex, ever smoking status and the first ten principal components of genetic ancestry.

Genome-wide association study. A GWAS was performed using Hail-0.2 (https://hail.is/) in the Google cloud. Variants were filtered to high-quality imputed variants (INFO score >0.4), with minor allele frequency >0.005, under Hardy–Weinberg equilibrium ($P \ge 1 \times 10^{-10}$), as previously performed. A Wald logistic regression model was used for analysis, adjusting for age, age², sex, ever smoking, principal components 1–10 and genotyping array. Significant, independent loci were identified using a threshold of significance of $P < 5 \times 10^{-8}$ and clumping in Plink-2.0, with an r^2 threshold of 0.1 across 1 Mb genomic windows, using the 1000-Genomes Project European reference panel. An additive mLOY polygenic risk score was developed, $\sum_{i=1}^{i=3}$ Beta × SNP_{ij}, where Beta is the weighting for each of the 156 independent genome-wide significant variants previously identified in the UKB male participants³⁰, and SNP_{ij} is the number of alleles (that is, 0, 1 or 2) for SNP_i in the female participant *j* in the UKB.

Cell-type enrichment analyses. We applied partitioned linkage disequilibrium (LD) score regression using LDSC⁴⁸ (v1.0.1) to perform enrichment analysis using the expanded mCA GWAS summary statistics, in combination with tissue-specific epigenetic and transcriptomic functionality annotations from GenoSkyline-Plus²². In addition to the baseline annotations for diverse genomic features as suggested in the LDSC user manual, we specifically examined the enrichment signals in two tiers of annotations of different resolutions: GenoSkyline-Plus functionality scores of seven broad tissue clusters (immune, brain, cardiovascular, muscle, gastrointestinal tract, epithelial, and others); and GenoSkyline-Plus functionality scores of 11 tissue and cell types in the immune cluster (listed in Fig. 6d).

Transcriptome-wide association and pathway enrichment analysis. A TWAS was carried out using the expanded mCA GWAS summary statistics in combination with the UTMOST⁴⁹ whole-blood model updated to GTExv8 (n = 670). Significant genes were identified using a Bonferroni cut-off of P < 0.05/15,625, or 3.2×10^{-6} . Pathway enrichment analysis was performed using genes that had P < 0.001 in the TWAS, using the Elsevier Pathways through the EnrichR web server⁵⁰.

Reporting Summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

UKB individual-level data are available by request via application (https:// www.ukbiobank.ac.uk). The mCA call set was previously returned to the UKB (return 2062) to enable individual-level linkage to approved UKB applications. Individual-level MGBB data are available from https://personalizedmedicine. partners.org/Biobank/Default.aspx, but restrictions apply to the availability of these data, which were used under institutional review board (IRB) approval for the current study, and so are not publicly available. The BBJ genotype data are available from the Japanese Genotype-phenotype Archive (JGA; http://trace.ddbj.nig.ac.jp/ jga/index_e.html) under accession code JGAD0000000123. Individual-level linkage of mosaic events can be provided by the BBJ project upon request (https:// biobankjp.org/english/index.html). FinnGen data may be accessed through Finnish Biobanks' FinnBB portal (www.finbb.fi). Individual-level CUB COVID-19 data, including the mCA call set, are available by application from https://www. ps.columbia.edu/research/core-and-shared-facilities/core-facilities-category/ columbia-university-biobank, but consent-related restrictions apply to the availability of these data, and data access requires separate IRB approval for the proposed data use. Aggregate data are also available upon reasonable request. Additionally, the full expanded mCA genome-wide association summary statistics

have been uploaded onto the LocusZoom website (https://my.locuszoom.org/ gwas/525823/). The present article includes all other data generated or analyzed during this study.

Code availability

A standalone software implementation (MoChA) of the algorithm used to call mCAs is available at https://github.com/freeseek/mocha. A pipeline to execute the whole workflow from raw files all the way to final mCA calls is available in WDL format for the Cromwell execution engine as part of MoChA. Code for all other computations is available upon request from the corresponding authors.

Author contributions

S.M.Z., S.-H.L., C.W., M.J.M. and P.N. performed statistical modeling of the UKB, FinnGen and MGB data. C.W. collected and analyzed the CUB data. S.M.Z. carried out the analyses of the GWAS and TWAS. P.-R.L. and G.G. carried out the mCA calls. M.J.M. and P.N. supervised the study. S.M.Z. and S.-H.L. drafted the manuscript. All authors critically reviewed the manuscript.

Competing interests

P.N. reports grants from Amgen during the conduct of the study and grants from Boston Scientific; grants and personal fees from Apple; personal fees from Novartis and Blackstone Life Sciences; and other support from Vertex outside the submitted work. P.T.E. has received grant support from Bayer AG and has served on advisory boards or consulted for Bayer AG, Quest Diagnostics, MyoKardia and Novartis, outside of the present work. S.M.Z., S.-H.L., M.J.M., G.G., and P.N. have filed a patent application (serial no. 63/079,74) on the prediction of infection from mCAs. G.G. and S.A.M. have filed a patent application (PCT/WO2019/079493) for the MoChA mCA detection method used in the present study. All other authors have no competing interests.

Extended Data Fig. 3 | Suggestive associations (P < 0.05) of expanded autosomal mCAs with specific incident infections by Cox proportional-hazards

models. Analyses are adjusted for age, age^2 , sex, smoking status, and principal components 1-10 of ancestry. Bonferroni correction was used to determine the level of statistical significance (0.05/20 or P < 0.0025). Overall estimates across studies are generated via fixed effect meta-analysis. Error bars show 95% confidence intervals. mCA = mosaic chromosomal alterations.

Extended Data Fig. 7 | Associations of expanded mCAs in the UK Biobank with COVID-19 and incident pneumonia. Associations of expanded mCAs with **a**. COVID-19 hospitalization across different adjustment models, and **b**. different COVID-19 phenotypes in fully adjusted logistic regression models. Adjustment models include (1) an unadjusted model, (2) a sparsely adjusted model which adjusts for age, age², sex, smoking status, and principal components of ancestry, and (3) a fully adjusted model which additionally adjusts for Townsend deprivation index, BMI, and the following comorbidities: Asthma, COPD, CAD, T2D, any cancer, and HTN. Bonferroni correction was used to determine the level of statistical significance. mCA = mosaic chromosomal alterations, COPD = chronic obstructive pulmonary disease, CAD = coronary artery disease, T2D = type 2 diabetes mellitus. **c**. Association of expanded mCAs with incident pneumonia stratified by sex, adjusted for age, age², sex (in the All model only), smoking status, and principal components of ancestry. Error bars show 95% confidence intervals. mCA = mosaic chromosomal alterations.

Extended Data Fig. 8 | Correlated associations of 63 independent genome-wide significant variants associated with expanded mCAs between different mCA categories in the UKB. Bonferroni correction was used to determine the level of statistical significance for the correlation analyses (P < 0.05/6 = 0.0083). Across all panels except for panel (a), the labeled genes represent genes attributed to variants that have P < 0.05 across the mCA categories in both axes. mCA = mosaic chromosomal alterations, r_n = Pearson correlation.

Extended Data Fig. 9 | Association of a mLOY PRS consisting of 156 previously identified²⁰ independent genome-wide significant variants associated with mLOY, with different expanded mCA categories in UKB Females. Error bands were derived from binomial proportion standard errors. mCA = mosaic chromosomal alterations, mLOY = mosaic Loss-of-chromosome Y, PRS = polygenic risk score.

Extended Data Fig. 10 | Pathway enrichment of TWAS results using the Elsevier Pathways. a. Top results from pathway enrichment analysis of the TWAS results using the Elsevier Pathways. **b**. Highlighting the GWAS locus-zoom plots for some of the TWAS genes implicated in the top pathways from panel a. Red boxes highlight the gene(s) with strongest association in the TWAS analyses. GWAS = genome-wide association study, TWAS = transcriptome-wide association study.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see our <u>Editorial Policies</u> and the <u>Editorial Policy Checklist</u>.

Statistics

For	all st	atistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.
n/a	Cor	firmed
	\boxtimes	The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement
\boxtimes		A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
	\boxtimes	The statistical test(s) used AND whether they are one- or two-sided Only common tests should be described solely by name; describe more complex techniques in the Methods section.
	\boxtimes	A description of all covariates tested
	\boxtimes	A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
	\boxtimes	A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
		For null hypothesis testing, the test statistic (e.g. F, t, r) with confidence intervals, effect sizes, degrees of freedom and P value noted Give P values as exact values whenever suitable.
\boxtimes		For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
\boxtimes		For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
	\boxtimes	Estimates of effect sizes (e.g. Cohen's d, Pearson's r), indicating how they were calculated
		Our web collection on <u>statistics for biologists</u> contains articles on many of the points above.

Software and code

Policy information about <u>availability of computer code</u>							
Data collection	Data was previously collected by the Biobanks invlved.						
Data analysis	A standalone software implementation (MoChA) of the algorithm used to call mCAs is available at https://github.com/freeseek/mocha. A pipeline to execute the whole workflow from raw files all th eway to final mCA calls is available in WDL format for the Cromwell execution engine as part of MoChA. Code for all other computations are available upon request from the corresponding authors. The following open-source software packages were also used: R-3.5, Eagle (v2.3.5), BOLT-LMM (v2.3.2), plink (v1.9), hail-0.2, GenoSkyline-Plus (http:// zhaocenter.org/GenoSkyline), UTMOST (https://github.com/Joker-Jerome/UTMOST), EnrichR (https://maayanlab.cloud/Enrichr/), LDSC v1.0.1						

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a <u>data availability statement</u>. This statement should provide the following information, where applicable: - Accession codes, unique identifiers, or web links for publicly available datasets

- A list of figures that have associated raw data
- A description of any restrictions on data availability

UKB individual-level data are available for request by application (https://www.ukbiobank.ac.uk). The mCA call set was previously returned to the UK Biobank (Return 2062) to enable individual-level linkage to approved UK Biobank applications. Individual-level MGBB data are available from https:// personalizedmedicine.partners.org/Biobank/Default.aspx, but restrictions apply to the availability of these data, which were used under IRB approval for the current study, and so are not publicly available. The BBJ genotype data is available from the Japanese Genotype-phenotype Archive (JGA; http://trace.ddbj.nig.ac.up/jga/

index_e.html) under accession code JGAD0000000123. Individual-level linkage of mosaic events can be provided by the BBJ project upon request (https:// biobankup.org/english/index.html). FinnGen data may be accessed through Finnish Biobanks' FinnBB portal (www.finbb.fi). Individual-level CUB COVID-19 data, including mCA call set, are available by application from https://www.ps.columbia.edu/research/core-and-shared-facilities/core-facilities-category/columbiauniversity-biobank, but consent-related restrictions apply to the availability of these data, and data access requires separate IRB approval for the proposed data use. Aggregate data is also available upon reasonable request. Additionally, the full expanded mCA genome wide association summary statistics have been uploaded onto the LocusZoom website (https://my.locuszoom.org/gwas/525823/). The present article includes all other data generated or analyzed during this study.

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	A total of 768,762 unrelated, multi-ethnic individuals across the UK Biobank (UKB) (N=444,199), Mass General Brigham Biobank (MGBB) (N=22,461), FinnGen (N=175,690), BioBank Japan (BBJ) (N=125,541), and Columbia University Biobank (CUB) (N=871). With the sample size of UKB, if we set alpha=0.05, estimated prevalence of mCA at 14.9%, and disease conditions with 2% prevalence, we can confidently detect 10% increase in risk >91.3% of the time using simple logistic regression. Additional cohorts add power to the meta-analysis and provide independent validation of our findings. Therefore, we believe that we are well-powered to detect subtle differences associated with mCA in common diseases.
Data exclusions	A total 768,762 unrelated individuals, passing genotype and mCA quality control criteria, and without hematologic cancer at time of blood draw for genotyping were analyzed. Quality control of genotyping and mCA calls prevents miscalssification, and removal of related individuals prevents confounding from relatedness
Replication	Replication of UKB analyses was performed in MGBB, FinnGen, and BBJ. Replication of UKB COVID-19 analysis was performed in FinnGen and CUB. Findings regarding various infections and expanded mCA in UKB replicated well in MGBB and were partially replicated in FinnGen. As for COVID-19 severity and expanded autosomal mCA, findings in UKB was replicated in FinnGen and CUB.
Randomization	We are conducting observational studies on clonal mCAs which is not a treatment and cannot be randomized
Blinding	NA; data was previously collected by the Biobanks

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.
